Abstract - Entity Linking (EL) is a task of aligning literal of a named-entity from an unstructured document to appropriate entities in a knowledge base. The main objective of EL in biomedical domain stems on construction of efficient computational models. This paper proposes a bootstrap approach based on uniformity perception and similarity computation to link entities from unstructured biomedical texts to ontologies. A rich semantic information and structures in ontologies are influenced by the proposed approach for similarity computation and entity ranking. The proposed approach address the Entity Linking in biomedical domain. The experiments show that our approach outperforms the existing state-of-the-art algorithms in terms of linkage accuracy.

Keywords - Entity Linking, Bootstrapping, Biomedical Literature.

I. BACKGROUND

Over the past years, there is an emergence of enormous amount of unexplained abbreviations and terminologies that leverages a major bottleneck in understanding scientific literature. Mining and linking significant facts/information from biomedical literature have great impact on knowledge discovery in biomedical domain. It is also very challenging even for domain experts to keep up with the large number of articles published [2]. For instance, supporting the modeling task by means of identifying the key proteins, and their behaviors and interactions. Hence, there is a need for advancements in methodologies for making sense of large amount of unstructured textual data which is explosively increasing. In order to facilitate it, specific way of analysis can be enabled, where phrases comprising of a distinct term or sequence of terms are automatically linked to entries in a knowledge base.

Here, the focus is on the task of Entity Linking (EL) from biomedical literature. Entity linking is a process that links different entities that refer to the same source of data. Such entities exists in many other fields such as semantic web, multimedia, personal profiling, publication, geography, etc. Our main aim is to automatically identify the prominent entity mentions from unstructured texts and linking them to terms described in a Knowledge Base (KB) and define in an ontology in order to enrich the text documents. These knowledge base and ontology terms are also referred to as reference entities. EL can helps human end user navigate biomedical literature and improve many other Natural Language Processing (NLP) tasks such as gene-disease association, gene-gene and protein-protein interaction event extraction [3, 4]. Entities enable semantic exploration of biomedical mentions, numerous information prerequisites can be encountered by recurring a list of entities, their properties, and/or their relations. Those entities can be utilized to identify unforeseen relations or functions and link the gap between unstructured and structured data.

Some recent works have been done on improving linkage performance using Machine Learning techniques [5,6]. However, it is laborious and effortful in building large-scale high-quality training set. Hence we propose a bootstrapping approach for entity linkage by utilizing semantics-based and similarity-based methods. For a given entity, our approach initially infers a set of semantically co-referent entities and then, iteratively expands this entity set using distinct classes. In order to improve the performance of the classifier bootstrapping [7] technique is used which is suitable for entity linkage due to the abundant uncertain entities. A publicly accessible ontologies in biomedical domain known as BioPortal [8] is utilized here. These ontologies consist of rich structures with declaratively defined semantic relations, along with comprehensive text descriptions provided by domain experts. We assume that multiple entities are semantically related in unstructured texts (i.e., they co-occur in the same sentence, are linked through dependency paths, or play certain semantic roles in the same event, etc.). Thereby address entity linking by means of uniformity perception by leveraging the global topical coherence and linking a set of relevant mentions simultaneously and generated labeled EL data through bootstrap approach.

Generally, there are two categories of EL algorithms namely collective inference and non-collective methods respectively [1]. Collective inference approaches influences concept mentions through supervised or graph based re-ranking methods. Besides they discourse the linking problem through exploiting the agreement between the mention document’s text and the context of the entities of the knowledge base. Graph based re-ranking models typically collects linking agreement information from training data and propagates to other nodes. Non-collective methods usually rely on prior knowledge and context similarity with supervised models. Ranking scores for each concept mentions are computed individually. Whereas, both these approaches requires large amount of manually labelled entity mentions in order to achieve a reasonable linking accuracy.
This paper presents a study on identifying prominent links between entities and label gene/protein-disease relations in PubMed and MEDLINE abstracts by using bootstrapping approach. Beginning with PubMed and MEDLINE abstracts, we first recognized gene/protein and disease entities using existing Natural Language Processing (NLP) tools such as Regex NER. Then we extract candidate gene/protein-disease pairs by mapping it with the existing ontology and knowledge base based on different levels of co-occurrence such as, abstract level, sentence level, phrase level and paragraph level. In order to find the most linked gene/protein-disease relations, we finally rank candidate gene/protein-disease pairs using Information Gain (IG). The evaluation using a manually annotated data set from Gene Ontology (GO) indicated that the Bootstrap method outperformed others. To our best knowledge, this is the first attempt that applied bootstrap approach to rank gene/protein-disease entity linking from biomedical literature.

II. METHODOLOGY

A. PROPOSED FRAMEWORK

A bootstrapping approach is proposed, in which it accepts the candidate entity as an input. The following section describes the methodological steps for our approach depicted in Fig. 1. The major goal of the paper is to link the identified entities to the concepts in the knowledge base. For a given biomedical text document as input, we extract the entity mentions and automatically construct a kernel, consisting of semantically co-referent entities, via uniformity perception on several gene/protein/disease vocabularies from ontologies. Then the kernel is expanded iteratively using distinct classes to probe different co-referent entities. The distinguishability of each class is learned with a statistical measure, revealing the importance of the class characterizing the co-referent entities and match the class by comparing the functions of those entities. Furthermore, frequent class combinations (i.e., the functions often used together) are mined to enhance entity labeling criterion in bootstrapping, so that the linkage accuracy can be improved. Entity mapping for an entity mention is assigned by measuring the popularity of an entity among all other candidate entities.

i. Input Documents

The development corpus is a subset of PubMed and Medline abstracts dealing with Huntington Disease and its genes. It was annotated with disease and gene relations, based on “etiology” and “clinical biomarker”. Beginning with PubMed and MEDLINE abstract collection. The initial step is the pre-processing which is done to determine entity boundaries in a text by sentence splitting and tokenization. Natural language processing incurs creation of a set of patterns to match the possible linguistic realizations of the individual facts. Due to this complexity, the preprocessing on structural input requires assigning parts-of-speech and features to words and idiomatic phrases. Annotated corpus drive construction of training data for machine learning that will filter out false positives from the dictionary-based results. These data are used for training and testing purposes. The input corpus consists of text related to Huntington Disease, gene names with their functions and all words related to neurogenetic disorders. The input corpus which is manually curated has 8998 sentences and 140481 words. Let, entity mentions \( u \in E \) are prominent phrases in the input biomedical text document. All classes, properties and individuals described in the ontologies \( r \in R \) are considered to be the reference entities. Relations based on sentence level and paragraph level are extracted based on co-occurrence are extracted. A list of candidate entities \( X \) are located from the biomedical dictionaries for each entity in the Context Graph \( CG \). Then we compute the importance score and link them by the bootstrap approach. Finally, we compute similarity scores for each entity/candidate pairs \( < u, x > \) and select the candidate with the highest score as the appropriate entity for linking.

![Figure 1 Work flow of the Bootstrap Entity Linkage](image)

ii. Entity Extraction

We apply the publicly available natural language processing tools for identifying prominent biomedical entities from unstructured texts to recognize the entity and ascribe it to a class or entity type. The occurrences of gene/disease entities in a text automatically identified by Gene/disease NER. Initially, a name tagger [9] is used to extract entity mentions. Regular expressions are used to join named entities that might have been considered separate by looking for intervening
prepositions, articles, and punctuation marks. After that, a shallow parser [10] is used to add noun phrase chunks to the list of entities. A parameter controls the minimum and maximum number of chunks per entity, in which by default one and four are considered and whether overlapping entities are allowed. The entity normalization process is characterized by representing entities’ names to their canonical names and by associating them with unique representations so as to help in solving issues resulting from variations in the synonym terms as well as the ambiguous abbreviations.

iii. Knowledge Base

A comprehensive Knowledge Base (KB) is developed based on the classes, characters and functions/properties present in the aggregated ontologies. Graph-based approach is used to construct the KB. We create a document for Triplet Construction in which each entity e is entity is described as as a set of triples t ∈ T. The knowledge base which is constructed from 300 biomedical ontologies from BioPortal [8], consist of the Triplets in which each entity is connected to other entities via a set of triples T. And these connections are regarded as edges of CG_KB, where, CG_KB is the Context Graph with respect to the Knowledge Base.

iv. Entity Mapping and Candidate Retrieval

We perform entity matching for all entity types based on regular expressions [11] using RegEx NER. It defines cascaded patterns over token sequences. Set of rules are defined for each entity type that expresses some patterns of entity mentions by exploring the corpora, and BIO labels are assigned to those patterns. Also, triples describing the entities are analyzed based on the properties such as: labels and names (e.g. rdfs:label), synonyms (e.g. synonym from gene ontology), aliases, and symbols (e.g. from Orphanet ontology). Thus providing more than 160 properties to map with its respective entity. Then we retrieve all the entities that are similar to the entity type that expresses the target genes t process can be encountered due noisy data.

v. Kernel Construction

A set of semantically co-referent entities u, mentioned as kernel of u is automatically inferred by using the functional aspects of gene and disease mined from biomedical dictionaries. We use Human Metabolome Database (HMDB) [12], Gene Ontology [13] and UniProt [14] as gene dictionary; Medical Subject Headings (MeSH) produced by US National Library of Medicine, and KEGG Disease [15] as disease dictionary. The training set is initialized by combining the candidate entity with the co-referent entities based on functional property, partial match and full match of the elements. Beside we assume that the correct entities are infer in the kernel. Yet, error accumulation in the bootstrapping process can be encountered due noisy data.

vi. Entity Labeling

Linking entities refers to the description of functions or target genes through which it is associated with the disease. Entity labeling is a task that deliberated for context graph in our experiments. Assume that the classification component in a given context graph is given a set of labels. The problem is simplified by initially constructing a network with only a single type of entity from the context graph. So that we introduce a link between two entities if they are connected to the same function and having introduced these entity-entity links delete all the functional nodes and the links originating from them in the context graph.

vii. Learning Distinct Classes

The most varied step is based on the hypothesis that co-referent entities share some similar functional aspects and a few functions are more essential for linking entities. For a given set of candidate entities with respect to u, we estimated a set of co-referent and non-co-referent entities together establish the training set of u. A pair of matched functions (partial/full) are chosen to hold the maximum distinguishability and is measured in terms of Information Gain [16]. Then assign a unique value to separate function in that class. Since, functional relations are involved in the iteration. Functional relations are extracted and compared with a string matching algorithm [17] for the entities given in the training set. Since, each entity is described in the dictionary that contains all phrases matching the string. If the similarity between the values are larger than a threshold, the related two functions are matched. The highest computational cost in the Boosting process is incurred due to functional aspect comparison. The learned functional classes reveal important characteristics of the mined biomedical literatures and enable to find new co-referent entities holding the same function. Additionally, we employ Apriori algorithm to find the frequent grouping of functions and refine them using heuristic rules beforehand. In each iteration, when a class is chosen and it belongs to some frequent class cluster, its counterpart in the group. Finally, the classes in the group with their associated value would be used together to obtain new links.

viii. Bootstrapping Algorithm

The proposed entity linkage algorithm is a kind of semi-supervised learning and is depicted in Algorithm 1. Given the kernel K(e) of an entity e, and a set of (uncertain) entities from the input document D, the goal is to incrementally learn the most distinct classes (steps 3-5) and use them to continue linking entities in X by retraining itself on an explained training set (steps 7-8).

Algorithm 1: Bootstrapping Biomedical Entity Linkage

Input: The kernel K of an entity e, a set X of Candidate entities in a set D of input documents.

Output: A set E of labelled co-referent entities for e.

1. Initialize two empty lists LP and LP, and print K to E;
2. Estimate a set N of non-coreferent entities for e such that N ⊆ X, |N| ≈ |E|;
3. The most distinct classes are selected (f_i, f_j) ∈ LP by Distinct(f_i, f_j) = IG(f_i, f_j) = E(T) − E(T(f_i, f))) such that
Precision takes into account all entity mentions that are linked by the system and determines how correct entity mentions linked by the entity linking system are. Precision is usually used with the measure recall, the portion of correctly linked entity mentions that should be linked:

\[
\text{recall} = \frac{|\text{correctly linked entity mentions}|}{|\text{entity mentions that should be linked}|} \tag{2}
\]

Recall takes into account all entity mentions that should be linked and determines how correct linked entity mentions are with regard to total entity mentions that should be linked. These two measures are used together in \( F_1 = \text{measure} \) to provide a single measurement for a system. \( F_1 = \text{measure} \) is defined as the harmonic mean of precision and recall:

\[
F_1 = \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}} \tag{3}
\]

Accuracy is calculated as the number of correctly linked entity mentions divided by the total number of all entity mentions. Therefore, here precision = recall = \( F_1 = \text{accuracy} \).

B. Results

The experimental evaluation were performed on a personal desktop with an Intel Core i5 3.1GHz CPU, 4 GB memory, Ubuntu 11.10 and Java 7. The datasets were stored on a server with two Xeon Quad 2.4 GHz CPUs, 64 GB memory, CentOS 6.4 and MySQL 5.6. We conducted our experiment using the evaluation dataset created by Zheng et al. (2015) which contains 208 linkable mentions extracted from several biomedical publications. Among all of the ontologies, there are more than 2 million entities and more than 50 million factual statements. We observed that for each mention, the candidate entity types are not as diverse. The kernel achieved the highest precision but the lowest relative recall, because some coreferent entities cannot simply be identified via uniformity perception. During bootstrapping, our approach estimated non-coreferent entities to measure distinctiveness and employed frequent combination of functions/relations between entities to enhance the selection criterion of functions/relations. The candidate “Neural Nucleus” a non-coreferent entity indirectly links to “Nerve Impulse”, due to frequent combination of relations it links to “Neural Nucleus” from candidates of coreferent entities enables the candidate entity “Cell Nucleus” to obtain the correct label and rank to link. Both of their contribution increased the overall accuracy of the proposed system. It is observed that, 64% of the correct links were inferred from the kernel, and 36% correct links were established through bootstrapping, in which 4% were of frequent combinations of relations.

The entity linking is to map an entity mentioned in an input text to the Knowledge Base, which consist of articles from PubMed and MEDLINE. The Bootstrap track gives a sample entity set which consists of 416 entities for developing. The test set consists of 3904 entities. 2229 of these entities cannot be mapped to Knowledge Base, for which the systems should
return NIL links. The remaining 1675 entities all can be aligned to Knowledge Base. We will firstly analyze the ranking methods with those non-NIL entities, and then with an additional validation module, we train and test with all entities including NIL link entities. We have shown our results for Biomedical Entity Linking system before and after bootstrapping of the biomedical entities in Table 2.

Table 2 Results for Bootstrapping Biomedical Entity Linking System

For example, given a sentence “The effects of the MEK inhibitor on total HER2, HER3 and on phosphorylated pHER3 were dose dependent.” It can link “HER2” to “ERBB2” in BioPortal and extract the class ‘Proto-Oncogenes→Oncogenes→Genes→Genome Components→Genome→Phenomena and Processes’ as the class and label the co-referent entities for this entity mention.

Figure 2 depicts the average precision and relative recall on the 50 testing entities with respect to the number of iterations, where the relative recall continuously rises up at the beginning and ascends slowly later. The result suggests that a small amount of distinct functions is accurate enough for entity linkage. If bootstrapping continues, some non-distinct functions would be chosen and cause decrease in precision. Based on the figure, we set the maximum number of iteration \( \tau = 4 \).

The empirical comparison has been made between the proposed Bootstrap approach and two other systems, which have several variations and it is hard to cover them all in our test. The Indexing + Similarity computation approach [18] leverages indexing techniques on a few important relations/functions to locate the candidate entities, and then combines various matchers to compute similarities between these entities and the input entities using the mention names of all the entities in our input corpus and used the TF_IDF model to compute the similarities between the descriptions of entities. The similarity threshold was set to 0.24 based on the best accuracy in our test. Class based learning approach identifies distinct functions/relations statistically w.r.t. different classes, and matches other entities under the same classes using the learned function/relations. We chose [19] in the test, which conducted uniformity perception to create a training set and ranked entities w.r.t. the information gain in different classes. Value similarities from top-5 function/relations were linearly aggregated with equal weighting, and the threshold was fixed to 0.14 according to the best accuracy.

Fig. 3 shows the precision and relative recall comparison between the proposed Bootstrap approach and the other two systems. It is observed that the Bootstrap approach achieved the best overall accuracy, while the class based learning largely depend on the sufficiency of the training sets, causing its accuracy varied between testing entities. The system based on Indexing + Similarity computation performed worse than the others, because it generated too many candidate entities with diverse functions/relation-values, and failed to decide a uniform threshold to eliminate wrong links.

V. CONCLUSION

We proposed a bootstrapping approach to entity linkage on biomedical domain. It automatically extract and link prominent entities from unstructured biomedical literatures to ontologies. The proposed Bootstrap approach is based on uniformity perception and similarity computation to link entities from unstructured biomedical texts to ontologies. Also bridges the gap between semantically coreferent entities and potential candidates. The experimental results show that our approach achieved superior precision and recall by comparing with the existing state-of-the-art algorithms with improved linkage accuracy. In future, we look forward to designing other semi-supervised learning approaches for entity linkage over biomedical domain.
